The World Health Organization estimates that worldwide, approximately 12 million new cases of tuberculosis (TB) are diagnosed each year. These 12 million cases of TB are a result of approximately 2 billion people, a quarter of the world's population, who are infected with the TB bacilli. In the United States, an estimated 4 million cases of TB are diagnosed each year. In 1997, the United States experienced a resurgence of TB resulting in over 20,000 cases, nearly twice as many cases as in the year before. In addition, approximately 14,000 TB patients died in 1997. Approximately 80% of these cases were caused by Mycobacterium tuberculosis. Chemotherapeutics in use today for the treatment of TB include isoniazid (INH), ethambutol (EMB), pyrazinamide (PZA), rifampin (RIF), and streptomycin (SM). However, the bacterium that causes TB is also developing resistance to all currently available chemotherapeutic drugs. A need therefore exists for new and improved anti-mycobacterial chemotherapeutics. Many patients infected with M. tuberculosis are also infected with HIV. HIV-infected patients are 50 to 100 times more likely to be infected with TB than HIV-negative individuals. It has been reported that the presence of active TB in the lungs of HIV-infected patients is associated with significantly accelerated progression of HIV disease to AIDS and increased risk of death. Furthermore, some reports suggest that anti-TB drugs may also inhibit the replication of HIV in vitro and in vivo and may improve the clinical status of HIV-infected patients. A need therefore exists for new and improved anti-mycobacterial chemotherapeutics that are effective against M. tuberculosis and have low toxicity. The lack of an effective vaccine combined with the inability of the currently available drugs to cure the infection results in a growing number of individuals who are chronically infected with TB. Some of these individuals are able to control the
